MINI PROJECT REPORT

REGISTER NUMBER	2117240070256
NAME	RITESH M.S.
PROJECT TITLE	FAKE NEWS DETECTION USING NAÏVE BAYES AND TF-IDF
DATE OF SUBMISSION	17/04/26
FACULTY IN-CHARGE	**Mrs. K. Fouzia Sulthana**

Signature of Faculty In-charge **Signature of HoD**

Internal Examiner **External Examiner**

INTRODUCTION

The rapid rise of digital media has made it easier for misinformation and fake news to spread quickly across social networks. Fake news threatens public opinion, democratic processes, and societal trust. Automated detection systems that classify news as real or fake are therefore crucial.

This project implements a Fake News Detection system using the Multinomial Naive Bayes classifier combined with Term Frequency-Inverse Document Frequency (TF-IDF) vectorization. Naive Bayes, based on Bayes' Theorem, assumes conditional independence between features and calculates the probability that a document belongs to each class (Real or Fake) based on word frequencies.

TF-IDF reflects the importance of a word in a document relative to the corpus, down-weighting common words (e.g., "the", "is") and emphasizing distinctive words, making it a more informative feature for text classification than simple word counts.

The system features a dark-themed interactive GUI (built with Tkinter and Matplotlib) where users can paste any news article and instantly get a verdict—Real or Fake—along with confidence scores and probability breakdowns. Three embedded dashboard tabs show the confusion matrix, performance metrics, and the most informative linguistic features learned by the model.

PROBLEM STATEMENT

Given a news article consisting of a headline and body text, automatically classify it as either Real or Fake using a machine learning pipeline trained on a large labelled dataset of news articles, and present the result to the user via an interactive graphical interface with a confidence score.

GOAL

- Train a Multinomial Naive Bayes classifier on the WELFake dataset (72,134 labelled articles) to distinguish real news from fake news.
- Achieve classification accuracy above 90% using TF-IDF with bigram features.
- Demonstrate that TF-IDF significantly outperforms Bag-of-Words vectorization on this task.
- Deploy the trained model in a real-time GUI application where users can paste arbitrary articles and receive instant predictions with confidence scores.
- Visualise model performance via confusion matrix, metric charts, and linguistic feature importance graphs.

THEORETICAL BACKGROUND

4.1 Naive Bayes Classifier

Naive Bayes is a family of probabilistic classifiers based on applying Bayes' Theorem with strong (naive) independence assumptions between every pair of features. For text classification, each word in the vocabulary is treated as an independent feature.

Bayes' Theorem states:

$$P(C \mid X) = (P(X \mid C) * P(C)) / P(X)$$

Where:

- P(C | X) is the posterior probability of class C given features X
- P(X | C) is the likelihood of features X given class C
- P(C) is the prior probability of class C
- P(X) is the evidence (constant across classes, ignored during classification)

For the Multinomial Naive Bayes variant, the log-probability of a document d belonging to class c is:

log P(c | d) = log P(c) + SUM_i [count(w_i, d) * log P(w_i | c)]

The conditional probability P(w_i | c) is estimated using Laplace (additive) smoothing to handle zero-frequency words:

P(w_i | c) = (count(w_i, c) + alpha) / (count(c) + alpha * |V|)

Where alpha is the smoothing parameter (set to 0.1 in this project), count(w_i, c) is the number of times word w_i appears in class c documents, count(c) is the total word count in class c, and |V| is the vocabulary size.

4.2 TF-IDF Vectorization

TF-IDF (Term Frequency-Inverse Document Frequency) transforms raw text into a numerical matrix where each cell represents the importance of a word to a document relative to the entire corpus.

Term Frequency (TF) for word w in document d:

TF(w, d) = count(w, d) / total_words(d)

Inverse Document Frequency (IDF) for word w across corpus D:

IDF(w, D) = log((1 + |D|) / (1 + df(w))) + 1

The final TF-IDF weight combines both:

TFIDF(w, d, D) = TF(w, d) * IDF(w, D)

In this project, sublinear TF scaling (log(1 + TF)) is applied to reduce the influence of extremely frequent terms, and bigrams (2-word sequences) are included alongside unigrams, enabling the model to capture phrases such as "breaking news" or "election fraud" as single features.

4.3 Literature Survey

Various machine learning and deep learning approaches have been explored for fake news detection. Shu et al. (2017) provided an early taxonomy of fake news and surveyed detection strategies. Ahmed et al. (2018) demonstrated that linear classifiers such as Naive Bayes and Linear SVM with TF-IDF achieve strong baselines on news datasets. Convolutional and Recurrent Neural Networks (CNN, LSTM) have been applied with word embeddings (Word2Vec, GloVe) and shown improvements on larger datasets, though at a significant computational cost. Transformer-based models such as BERT (Devlin et al., 2019) achieve

state-of-the-art performance but require substantial GPU resources and are impractical for a lightweight desktop application.

4.4 Justification for Algorithm Choice

- Multinomial Naive Bayes is specifically designed for discrete count features such as word frequencies, making it the natural choice for TF-IDF text classification.
- Training is extremely fast (O(n) in dataset size), enabling the model to load within seconds when the GUI application starts.
- Despite its simplicity, it achieves over 93% accuracy on this dataset, competitive with far more complex models.
- The probabilistic output (predict_proba) provides interpretable confidence scores directly useful to the GUI user.
- Compared to Bag-of-Words, TF-IDF with bigrams reduces noise from high-frequency stop words and captures multi-word patterns unique to fake news language.

ALGORITHM EXPLANATION WITH EXAMPLE

Consider a simplified corpus of 4 training articles:

Article (simplified)	Label	Key TF-IDF Features
"Government passes new budget bill"	**Real**	budget, bill, government
"Scientists SHOCKED: vaccines cause mind control"	**Fake**	shocked, mind control, secret

Step 1 - TF-IDF Vectorization: Each article is converted into a sparse vector. The word "shocked" has high TF-IDF weight in the fake article because it appears rarely in real news, giving it a high IDF value.

Step 2 - Prior Probability: With a 50/50 class split, P(Real) = P(Fake) = 0.5. With the WELFake dataset, P(Real) = 0.491 and P(Fake) = 0.509.

Step 3 - Likelihood: The model computes P(word | Real) and P(word | Fake) for every word in the vocabulary using Laplace-smoothed counts from training data.

Step 4 - Classification: For a new article, the class with the highest log-posterior is assigned. For example, an article containing "shocking truth hidden by government" triggers high P(Fake | article) due to the log-probability contributions of sensationalist terms.

Step 5 - Confidence: predict_proba returns [P(Real), P(Fake)]. A score of [0.08, 0.92] means the model is 92% confident the article is Fake.

IMPLEMENTATION CODE AND DATASET USED

Category	Description
Dataset Name	WELFake Dataset
Domain	Natural Language Processing (NLP)/Journalism
Objective	Binary Classification (Real vs Fake)
Data Source	Public – 4 datasets from Kaggle
Number of Samples	72, 134 labelled news articles
Data Type	Text
Instance Description	One complete news article (title + body text)
Features (Inputs)	Title (str), text (str) – combined into a single text field
Feature Types	Text (converted to numerical TF-IDF vectors)
Target Variable	Label – 0 = Real, 1 = Fake
Number of Classes	2 (Binary Classification)
License	Public / Open Access (Kaggle)
Version	1.0

CODE:

```
import os, re, threading, warnings

TF-IDF Improvement	+2.3% over BoW

RESULTS AND FUTURE ENHANCEMENT

8.1 Results Summary

The Multinomial Naive Bayes model with TF-IDF bigram features achieves approximately 93.5% accuracy on the WELFake test set, outperforming the Bag-of-Words baseline by over 2 percentage points. The confusion matrix reveals that false negatives (real articles misclassified as fake) and false positives (fake articles misclassified as real) are approximately balanced, indicating no significant class bias. The most predictive fake-news features include sensationalist terms and conspiratorial phrases, while real-news features include formal journalistic language and source citations.

8.2 Comparison with Other Approaches

- Linear SVM with TF-IDF achieves similar accuracy (~94%) but does not natively provide probability estimates, making it less suitable for a confidence-score GUI.
- Logistic Regression achieves ~93% and is comparable, but Naive Bayes trains significantly faster, making it more responsive for on-startup training in a desktop app.
- LSTM / BERT models can reach 96-98% accuracy but require GPU resources, large dependencies, and minutes of training time — impractical for a lightweight classroom project.

8.3 Future Enhancements

- Integrate web scraping so users can input a URL and have the article fetched and analyzed automatically.
- Add source credibility scoring by cross-referencing the news outlet against a known blacklist/whitelist.
- Fine-tune a DistilBERT transformer model for improved accuracy while keeping inference fast enough for real-time use.

- Extend to multilingual fake news detection using multilingual embeddings (e.g., XLM-RoBERTa).
- Deploy as a browser extension that highlights fake news inline while the user browses news websites.
